**Abstract:** This paper uses forecasts from the European Central Bank’s Survey of Professional Forecasters to investigate the relationship between inflation and inflation expectations in the euro area. We use theoretical structures based on the New Keynesian and Neoclassical Phillips curves to inform our empirical work and dynamic model averaging in order to ensure an econometric specification capturing potential changes. We use both regression-based and VAR-based methods. The paper confirms that there have been shifts in the Phillips curve and identifies three sub-periods in the EMU: an initial period of price stability, a few years where inflation was driven mainly by external shocks, and the financial crisis, where the New Keynesian Phillips curve outperforms alternative formulations. This finding underlines the importance of introducing informed judgment in forecasting models and is also important for the conduct of monetary policy, as the crisis entails changes in the effect of expectations on inflation and a resurgence of the “sacrifice ratio”.

**Keywords:** inflation expectations, survey of professional forecasters, Phillips curve, Bayesian, financial crisis.

## **Non-technical summary**

This paper focuses on inflation and inflation expectations in the euro area. We analyze: 1) whether inflation expectations have a sizable and measurable effect on inflation in the euro area; 2) whether this effect can be considered as robust evidence, considering the strong amount of uncertainty about how to precisely model inflation and the heterogeneous results found in the literature. Furthermore, and following the recent crisis, we try to assess 3) whether the link between inflation and expectations has changed in recent years; and 4) whether the increased inflation uncertainty observed during the crisis is likely to play a relevant role in determining future inflation.

To address these issues, we use direct measures of inflation expectations provided in the European Central Bank's Survey of Professional Forecasters and model these jointly with inflation itself as well as a standard set of predictors. In order to econometrically estimate our set of models, we require a modelling framework which allows for many predictors as well as allowing for model change. Accordingly, our econometric methods use dynamic model averaging (DMA). The previous literature uses DMA in the context of one equation regression models. In the present paper, we extend these methods for use with VARs.

The regression results tell a consistent story. It is forward looking expectations that are important in the Phillips curve, a finding in line with the New Keynesian Phillips curve. Our DMA results also suggest that the importance of forward looking expectations is greater at the end of our sample, at the time of the financial crisis and ensuing recession. The change in importance of other regressors provides, in our opinion, a coherent explanation of the determinants of inflation dynamics before and during the crisis. First of all, the oil price shocks affecting prices as of 2006 are clearly visible in the increased importance of the oil variable in the period 2006/2008. In this period of strong and unpredictable shocks, sizeable errors in the agents' expectations reduce their inclusion probability. At the same time, and given the more unpredictable inflation developments, the importance of the first lag of inflation increases, leading to models somewhat closer to a random walk. When the global crisis hits in 2008, this time in the context of coherent macroeconomic developments, the regressors representing fundamentals seem to be again more important, either as direct explanatory variables (short and long interest rates and financial markets developments) or through current expectations of future inflation, which are computed by the agents keeping it into account a much wider information set than the one included in our regressions.

The SPF is a relatively new data source and, thus, econometric methods designed to deal with the short data span were required. However, our empirical exercises suggest that, even with this short data span, there is information in the SPF than can be fruitfully used by macroeconomists and policymakers.

# 1 Introduction

Expectations are essential for determining economic outcomes and for policymakers. Economic theory suggests that inflation, in particular, should be heavily influenced by expectations of future inflation. Producers' and consumers' decisions are taken on the basis of inflation expectations and from these decisions prices and real outcomes are determined. Central banks are very interested in expectations: anchoring long-term inflation expectations is crucial for maintaining price stability. And inflation expectations are an essential component to be monitored, providing essential information when conducting monetary policy in a forward-looking manner. This is because they determine the overall effect of exogenous shocks on prices, both in size and length, and the sacrifice in terms of output necessary to bring inflation to target once it has drifted away.

Quantitative information on the uncertainty surrounding the macroeconomic outlook is also an important part of the macroeconomic information set used by economic policy-makers and central banks (see, for example, the discussions in Tay and Wallis 2000, Wallis 2003, or Sims 2002), and may be an additional factor in driving financial market variables, households' and firms' decision-making and ultimately inflation outcomes. Indeed, uncertainty plays a role in several models of consumer and investor behavior (e.g. Lahiri et al. 1988, Giordani and Söderlind 2003, and D'Amico and Orphanides, 2008).

This paper focuses on the relationship between inflation and inflation expectations in the euro area. We adopt specifications motivated by macroeconomic theory and, in particular, the New Keynesian and Neoclassical Phillips curves. We analyze: 1) whether inflation expectations have a sizable and measurable effect on inflation in the euro area; 2) whether this effect can be considered as robust evidence, considering the strong amount of uncertainty about how to precisely model inflation and the heterogeneous results found in the literature. Furthermore, and following the recent crisis, we try to assess 3) whether the link between inflation and expectations has changed in recent years; and 4) whether the increased inflation uncertainty observed during the crisis is likely to play a relevant role in determining future inflation. The last two points are of interest, as the data on one year ahead

expectations and inflation in the last decade show that during the crisis, and in contrast to earlier history, the changes in inflation increased and large forecast errors were made, while forecast uncertainty went up substantially.

To address these issues, we use direct measures of inflation expectations provided in the European Central Bank's Survey of Professional Forecasters and model these jointly with inflation itself as well as a standard set of predictors. This choice is appealing for many reasons. First, by using measured expectations we are not imposing any hypotheses on expectations themselves, in particular we do not need to assume rational expectations (or any specific form of non-rationality), while maintaining at the same time the micro-foundations of price adjustment behavior as described in the new Keynesian theory. Second, we can compare the neoclassical Phillips curve with the new Keynesian Phillips curve without imposing one of the two a priori. Finally, when we turn to bivariate VARs, we are able to make useful inference about the dynamic relationship occurring between inflation and expectations.

In order to econometrically estimate our set of models, we require a modelling framework which allows for many predictors as well as allowing for model change. However, such a framework risks being over-parameterized since the SPF was only launched in 1999 and, thus, the sample is quite short. Accordingly, our econometric methods use dynamic model averaging (DMA, see Raftery, Karny and Ettlér 2010). DMA is a relatively new statistical method which, in a regression context, lets the set of explanatory variables switch over time. This contrasts with conventional nonlinear time series methods (e.g. time varying parameters, TVP, or Markov switching models) which typically allow for coefficients to change within a single model. In a macroeconomic forecasting exercise involving a large set of predictors, Koop and Korobilis (2011) find that DMA forecasts well (much better than comparable TVP models). By switching between different highly parsimonious models, it avoids being over-parameterized, at the same time allowing for the regime changes which have occurred in the economy. These considerations suggest that DMA is an appropriate method for use in the present application. The previous literature uses DMA in the context of one equation regression models; in this paper, we extend these methods for use with VARs.

The structure of the paper is as follows. Section 2 discusses the empirical problems in estimating the relationship between inflation and inflation expectations using the Phillips curve, and section 3 those of measuring ex-

pectations. Section 4 is the main part of the paper, describes and applies the econometric technique and shows the main results. Section 5 summarizes the findings and concludes.

## 2 The Theoretical Relationship Between Inflation and Inflation Expectations

The existence of a strong relationship between inflation and inflation expectations is nowadays a standard component of any theoretical framework. Abstracting from model specificities, this relationship is generally modeled through some version of the Phillips curve. Three formulations of the Phillips curve are popular in the literature.

In the Neoclassical Phillips curve (Phelps 1968, Friedman 1968, Woodford 2003) a fraction of prices are set one period in advance, while the others are fully flexible. Thus, inflation is influenced by the previously expected current inflation and the Phillips curve can be formulated as:

$$\pi_t = \alpha\pi_{t-h}^e + \beta X_t \quad (1)$$

where  $\pi_t$  is inflation at time  $t$ ,  $\pi_{t-h}^e$  is inflation at time  $t$  as expected in  $t-h$ ,  $X_t$  is a vector of explanatory variables including at least a measure of capacity utilization (e.g. the output gap or unemployment) as well as other regressors and  $\alpha$  and  $\beta$  are parameters to be estimated. In the empirical section of this paper we have  $h = 4$ , consistent with quarterly data and expectations one year ahead.

In the New Keynesian Phillips curve, described for instance in Calvo (1983), only a fraction of firms can adjust prices in each period. These firms choose to adjust them optimally, taking into account expected future price developments and the probability that they may not be able to adjust their prices in the following periods. A general formulation for the New Keynesian curve is:

$$\pi_t = \alpha\pi_{t+h|t}^e + \beta X_t \quad (2)$$

where current expectations of future inflation  $\pi_{t+h|t}^e$  determine the current inflation rate  $\pi_t$ .

Neither the Neoclassical or the New Keynesian Phillips curves performed very well in empirical terms. To solve this problem, the hybrid Phillips curve

(Gali and Gertler, 1999) introduces lagged inflation in order to allow for inflation persistence. This formulation can be derived on the hypothesis that at every period a fraction of firms sets prices optimally, as in Calvo, while the rest use a backward-looking rule based on recent history of aggregate prices. The hybrid New Keynesian Phillips curve can be formulated as:

$$\pi_t = \alpha\pi_{t+h|t}^e + (1 - \alpha)\pi_{t-1} + \beta X_t \quad (3)$$

In this form of the curve both current expectations of future prices and past inflation determine current inflation. The intrinsic persistence of inflation in the hybrid curve contrasts with the previous formulations, where any persistence is stemming from expectations. The existence of different versions of the curve is a first element of complexity we must take into account when trying to bring the theory to the data.

A second important factor is the relationship with inflation uncertainty. The idea can be traced back to Friedman (1977), who suggested that higher average inflation could be associated with higher inflation uncertainty. This idea was developed by Ball (1992), who proposes a model in which higher inflation leads to increasing uncertainty over the monetary policy stance. The opposite view of a negative effect of inflation on its uncertainty is taken by Pourgerami and Maskus (1987), who point out that in an environment of accelerating inflation agents may invest more resources in inflation forecasting, thus reducing uncertainty (see also Ungar and Zilberfarb, 1993). Causality from inflation uncertainty to inflation is a property of models based on the Barro–Gordon setup, such as the one due to Cukierman and Meltzer (1986). A more recent model that has uncertainty at its heart is the sticky-information model proposed by Mankiw and Reis (2002).

### 3 Which expectations?

In addition to uncertainty about the formulation of the Phillips curve, macroeconomists have diverging opinions about an essential element of the curve itself: the expectations. Expectations, if measured correctly, are probably the most important variable required in the estimation of the Phillips curve. Among theorists, there is disagreement on how to model and measure expectations. Until the mid-1970s, expectations were generally modeled as backward looking, adaptive processes. Backward looking expectations naturally imply persistence in inflation, thus explaining what seems to be a

feature of inflation developments. However, backward looking expectations also imply systematic expectation errors. The introduction of rational expectations rectified this inconsistency, assuming that expectation errors are non-systematic. However, modelling inflation assuming rational expectations has not performed well in practice. Today, mainstream models featuring rational expectations are more and more complemented by frameworks featuring alternative formulations. Recent research has focused on the formation of expectations through learning processes, where agents continuously improve their knowledge of the economy. Like rational expectations, the formation of expectations through learning is consistent with forward looking behavior, but learning also gives rise to persistence in expectations, which is a desirable feature.

On the empirical side, following Gali and Gertler (1999), most econometric estimates of the New Keynesian Phillips curve simply estimate under the assumption of rational expectations. Taking advantage of the fact that under rational expectations forecasting errors are assumed to be unpredictable, these estimates use data on future inflation outcomes. GMM estimation methods are often used. This technique confronts the problem that finding an instrumental variable which is at the same time outside the Phillips curve but has good predictive power for future inflation is difficult in practice. Additional difficulties of identification are discussed in Pesaran (1987), Ma (2002), Mavroeidis (2005) and Kleibergen and Mavroeidis (2009). For instance, Kleibergen and Mavroeidis (2009) find parameters of the hybrid New Keynesian Phillips curve to be weakly identified and argue that this partially accounts for the conflicting estimates reported in the literature. However, they find enough identification occurs so as to make some empirical conclusions (e.g. they find that forward-looking dominates backward-looking behavior). Finally, assuming rational expectations sidesteps without solving it the issue of the relationship between expectations and inflation and is more useful for exploring the output gap parameters.

The empirical literature just discussed treats inflation expectations as being unobserved (thus, requiring the rational expectations assumption and clever justification of instrumental variables, etc.). In this paper we choose to abandon this assumption and to base our analysis on measured inflation expectations. This approach has several advantages for our purposes. First, by using measured expectations we are not imposing any hypotheses on expectations themselves. In particular we do not need to assume rational expectations or choose any specific form of non-rationality, while maintain-

ing at the same time the micro-foundations of price adjustment behavior as described in the new Keynesian theory. Using measured expectations we can empirically assess the importance of timing of expectations in the Phillips curve, therefore comparing the neoclassical Phillips curve with the new Keynesian Phillips curve without imposing one of the two a priori. Finally, when we turn to bivariate VARs, we are able to make useful inference about the dynamic relationship occurring between inflation and expectations, and analyze to which extent the persistence of inflation expectations determines the persistence of inflation itself.

Measured inflation expectations are typically collected through surveys. Particularly in the US, surveys of experts or the public at large have been used to empirically proxy inflation expectations. Examples include Ang, Bekaert and Wei (2007), Leduc, Sill and Stark (2007) and Mehra and Herrington (2008). The first of these is a forecasting paper which finds inflation surveys to be better predictors of inflation than a range of other alternatives. The latter uses inflation surveys within a structural VAR model of the US economy to address issues of importance for macroeconomic policy. Clark and Davig (2008) survey the US literature and presents results from a tri-variate structural VAR for inflation, short-term and long-term inflation expectations. They find that shocks to long-term inflation expectations have a strong effect on inflation, while the effect of shocks to short-term expectations is minor.

Focusing on the euro area, Paloviita (2008) compares different specifications of the Phillips curve. Paloviita and Virén (2009) estimate a VAR model of inflation, inflation expectations and output gap that allows for an analysis of the interrelationship between these variables.

A similar shift towards the use of survey data can be observed in relation to studies involving inflation uncertainty. Early work involved estimates of uncertainty based on ARCH models (see Caporale, Onorante and Paesani 2010, for a recent treatment). This literature has been progressively complemented by studies using disagreement in survey data as a measure of inflation uncertainty (e.g. Davis and Kanago 1996, Bomberger 1996, Hayford 2000 and Giordani and Söderlind, 2003).

The measure of inflation expectations used in this paper is the Survey of Professional Forecasters (SPF). The SPF, launched by the European Central Bank (ECB) in the last quarter of 1998, immediately following the establishment of the single currency, asks a panel of approximately 75 forecasters located in the European Union (EU) for their short- to longer-term expecta-

tions for euro area inflation, growth and unemployment (see Garcia 2003 for details). In this paper, we focus on inflation expectations. An important feature of the SPF is that it provides information for the euro area on a rolling window basis (in other words, always the same number of quarters ahead). It also provides with several measures of uncertainty. These measures of uncertainty are strongly correlated; our empirical work uses disagreement among forecasters.

Not only does the survey of professional forecasters provide important information relevant to the conduct of monetary policy, it also has important information content for future development of inflation. The statistical properties of the survey of professional forecasters have been analyzed by Bowles et al. (2007) and in Garcia and Manzanares (2007). The authors find that the one year ahead inflation forecast slightly underestimated inflation, a result that they attribute to the fact that euro area has been affected by a number of upward shocks to prices (for example, forecast errors are correlated with oil and food price movements) and to a corresponding slight overestimation of the unemployment rate. They also find that the SPF forecasts for inflation are systematically more accurate than naïve forecasts and contain information about the future beyond what is already contained the most recent data.

In contrast to the growing amount of literature related to the Survey of Professional Forecasters in the United States, the European SPF has not been widely used in economic analysis. Some examples of recent contributions include Genre et al. (2010), Andrade and Le Bihan (2010) and Gnan et al.(2010). Indeed, a problem with this survey is that it has been available for a relatively short time span. And this time span has covered a time of a great deal of macroeconomic instability, including the recent financial crisis. This consideration necessitates the use of econometric methods which allow for regime change, but at the same time ensuring parsimony so as to try and obtain relatively precise inferences with a short data set. It is to this we now turn.

## 4 Econometric Methods

### 4.1 General Considerations

All of our econometric methods will be extensions of regressions or VARs. Univariate, regression-based specifications are simpler and more parsimonious, allowing us to directly estimate equations motivated by the hybrid New Keynesian and Neoclassical Phillips curves. A bivariate specification, modelling inflation and an expectation of inflation jointly, will additionally allow us to investigate whether there are feedbacks from inflation to expectations (see, e.g., Clark and Davig, 2008). In this paper, we consider both univariate and bivariate specifications. It is worthwhile from the outset to make clear the dependent ( $y_t$ ) and explanatory variables we use. In our regressions, the dependent variable is inflation,  $y_t = \pi_t$  (also named INFL).

Our extensions of VARs will be bivariate ones. Motivated by the Neoclassical Phillips curve in (1), some of our VARs involve  $y_t = \left(\pi_{t|t-4}^e, \pi_t\right)'$  (also named SPF\_NEO). Motivated by New Keynesian Phillips curve in (2), the remainder of our VARs use  $y_t = \left(\pi_{t+4|t}^e, \pi_t\right)'$  (also named SPF\_KEY). We use annualized HICP inflation (the year-on-year percentage change in the HICP) as the SPF relates to this inflation definition.

Our explanatory variables will differ by specification, but motivated by a wish to investigate whether forward or backward looking expectations are important for inflation, our regressions include  $\pi_{t+4|t}^e$  and  $\pi_{t|t-4}^e$  as explanatory variables and our VARs will include appropriate lagged dependent variables as explanatory variables. In addition, we include other exogenous explanatory variables (labelled  $X_t$  in equations 1, 2 and 3). The literature on the so-called generalized Phillips curve is too voluminous to survey here (see, e.g., Stock and Watson, 2008), but a message coming out of this literature is that there are several potential explanatory variables for inflation. Any model which omits such explanatory variables risks mis-specification and risks misunderstanding the relationship between inflation and inflation expectations. Another message from the literature (see, e.g., Koop and Korobilis 2011, for an application using US data, or the discussion in Fuhrer et al, 2010) is that the determinants of inflation change over time. This is especially important in light of the recent financial crisis. The unprecedented size and length of the recent recession has not been matched by a corresponding decrease in inflation, raising the possibility of a shift in the Phillips curve in the euro

area. Indeed, a shift has been also found in recently estimated models with changing coefficients (Caporale et al., 2010). As a consequence, we want to allow for the relationship between inflation and its expectation to potentially change over time. This will allow us to investigate whether the recent financial crisis can be considered a structural change in the Phillips curve.

As far as the relationship between inflation and expectations is concerned, the first years of the EMU were characterized by inflation and expectations solidly anchored at about 2%. However, during the current downturn, with headline inflation close to negative for the euro area, inflation expectations, even though lower than their long-run average, remained close to historical values. Whether this is also the signal for a change in structure of the relationship between the two is an interesting question for our empirical investigation.

Accordingly, including a rich set of predictors for inflation, but using an econometric method which allows for change over time is essential. In this paper, we use the following set of eight euro area predictors which includes a wide range of variables thought to be important by theory or found to be important in other studies:

1. ULC: unit labour costs (annual percentage change), seasonally adjusted, ESA95 National Accounts.
2. GAP: output gap, Economic Outlook (OECD).
3. UNEMP: standardized unemployment rate in percentage of civilian workforce, seasonally adjusted, Eurostat.
4. SPF\_VAR: inflation uncertainty as measured by disagreement among forecasters (see Section 3).
5. OIL: oil price (annual percentage change, Brent crude).
6. ISHORT: Euribor 3-month interest rate, historical close.
7. ILONG: euro area 10-year government benchmark bond yield.
8. STOX: Dow Jones Eurostoxx 50 Index (percentage change), historical close, provided by Reuters.

The relatively short data span for the SPF poses problems for developing statistical methods which achieve the goals we have just set out. If we use a very flexible specification which includes many predictors and allows for breaks (or other sorts of coefficient change), it will be difficult to obtain reasonable estimates: the number of parameters will simply be too large relative to the number of observations. On the other hand, if we work with too simple models (e.g. with few explanatory variables and/or coefficients that are constant over time), then we risk working with mis-specified models and failing to address our research questions of interest. What we do in this paper is use a method called Dynamic Model Averaging (DMA) which, from a flexible specification, allows us to uncover parsimonious specifications which can change over time.

## 4.2 Dynamic Model Averaging

DMA is developed in Raftery, Karny and Ettlter (2010) and used in Koop and Korobilis (2011) and the reader is referred to these papers for complete details (see also the appendix to this paper). Here we describe the basic ideas in the context of the regression model where  $X_t = (x_{1t}, \dots, x_{kt})'$  contains  $k$  explanatory variables:

$$y_t = \beta_0 + \sum_{i=1}^k \beta_i x_{it} + \varepsilon_t$$

where  $\varepsilon_t$  is i.i.d.  $N(0, \sigma^2)$ . Within this general model, we can define  $K = 2^k$  restricted models which contain subsets of the  $k$  explanatory variables. The dynamic aspect of DMA arises since it allows for a different model to hold at each different time period. Let  $L_t \in \{1, 2, \dots, K\}$  denote which model holds at time  $t$  and  $q_{t|s,j} = \Pr(L_t = j | y^s)$  be the probability that model  $j$  holds at time  $t$  given information through time  $s$ . DMA is a recursive algorithm which allows for the calculation of  $q_{t|t,j}$  and  $q_{t|t-1,j}$  for  $j = 1, \dots, K$ . In an estimation exercise such as the one in this paper (e.g. estimating coefficients or impulse responses)  $q_{t|t,j}$  can be used to carry out model averaging in a time varying fashion.  $q_{t|t-1,j}$  can be used in a similar fashion when forecasting  $y_t$  given information through time  $t - 1$ .

Note that, since  $K$  can be large and DMA allows for a different model to hold in every time period, the computational burden can be enormous. That is, with  $T$  observations,  $2^{Tk}$  possible combinations of models at various times

can exist. Exhaustive evaluation of all these combinations is computationally infeasible unless  $k$  and  $T$  are both small. The contribution of Raftery et al. (2010) was to develop a clever approximation, involving a so-called forgetting factor,  $\alpha$ , which reduces the computational burden enormously (in essence, it only requires recursive estimation of  $K$  models).

To explain DMA in a bit more detail, we introduce notation where  $y^s = (y_1, \dots, y_s)'$  and, thus,  $p_k(y_t|y^{t-1})$  is the predictive density for model  $k$ . Note that the predictive density in the regression model has a familiar form that can easily be evaluated. The predictive density appears in the model updating equation of:

$$q_{t|t,j} = \frac{q_{t|t-1,j} p_j(y_t|y^{t-1})}{\sum_{l=1}^K q_{t|t-1,l} p_l(y_t|y^{t-1})}. \quad (4)$$

If we knew  $q_{t|t-1,j}$  then, starting with  $q_{0|0,j}$  we could recursively calculate the key elements of DMA:  $q_{t|t,j}$  and  $q_{t|t-1,j}$  for  $j = 1, \dots, K$ . Raftery et al. (2010) provide this missing link by using the approximation:

$$q_{t|t-1,j} = \frac{q_{t-1|t-1,j}^\alpha}{\sum_{l=1}^K q_{t-1|t-1,l}^\alpha}. \quad (5)$$

A detailed justification for why this is a sensible approximation is given in Raftery et al. (2010). Suffice it to note here that it implies:

$$\begin{aligned} q_{t|t-1,j} &\propto [q_{t-1|t-2,j} p_j(y_{t-1}|y^{t-2})]^\alpha \\ &= \prod_{i=1}^{t-1} [p_j(y_{t-i}|y^{t-i-1})]^\alpha. \end{aligned}$$

Thus, model  $j$  will receive more weight at time  $t$  if it has fit well in the recent past (where fit is measured by the predictive likelihood,  $p_j(y_{t-i}|y^{t-i-1})$ ). The interpretation of “recent past” is controlled by the forgetting factor,  $\alpha$ . Thus, if  $\alpha = 0.99$  (our benchmark value and also the value used by Raftery et al., 2010), forecast performance five years ago receives 80% as much weight as forecast performance last period (when using quarterly data). If  $\alpha = 0.95$ , then forecast performance five years ago receives only about 35% as much weight. These considerations suggest that we focus on the interval  $\alpha \in (0.95, 0.99)$ .

In our short data set, the potential advantages of DMA are clear. We can include a large number of explanatory variables, but DMA can attach weight to more parsimonious models, lessening the problems caused by our short data span.<sup>1</sup> Furthermore, DMA allows for model change. It can capture cases where certain explanatory variables are important in certain periods, but not in others. Given our application, which spans the time from the introduction of the euro through the recent financial crisis, allowing for such change is likely crucial. In short, DMA is likely to meet our needs for a statistical framework involving many explanatory variables and allowing for change in an effective and parsimonious way.

We have described DMA in terms of the regression model. We use this in our univariate empirical exercises. In our multivariate empirical work, we extend the existing literature by developing DMA methods for multivariate models such as VARs. Details are provided below and in the appendix.

We note also that, in the past, DMA has been done in the context of time-varying parameter (TVP) models where the coefficients evolve as  $\beta_{it} = \beta_{i,t-1} + u_t$ . Given our short data span and need to keep the model as parsimonious as possible, we do not consider this extension. In the empirical application of Koop and Korobilis (2011), it is found that allowing for models to switch over time is of greater empirical benefit than allowing for coefficients to evolve in a TVP fashion and, thus, we focus on model change rather than parameter change.

### 4.3 Regression-Based Methods

We begin by investigating issues relating to the Neoclassical and New Keynesian Phillips curves in the following regression specification:

$$\pi_t = \alpha_0 + \alpha_1 \pi_{t|t-4}^e + \alpha_2 \pi_{t+4|t}^e + \sum_{i=1}^8 \beta_i x_{it} + \sum_{i=1}^p \gamma_i \pi_{t-i} + \varepsilon_t \quad (6)$$

where  $x_{it}$  for  $i = 1, \dots, 8$  are the eight explanatory variables listed in Section 4.1. The coefficients  $\alpha_1$  and  $\alpha_2$  are of most interest since they shed light on the backward or forward looking nature of the Phillips curve. Note that including lags of the dependent variable does not shorten our data span (i.e. it is only the SPF variables for which the time span of the data is short).

---

<sup>1</sup>See Koop and Korobilis (2011) for evidence that DMA can effectively find very parsimonious models.

Given the timing convention of the SPF variables in (6) all of our regressions use data from 1999Q4 to 2011Q2, regardless of choice of lag length.

We begin by presenting OLS estimates of (6) for  $p = 4$ . BIC's indicate that this is the preferred lag length (although the BIC for  $p = 1$  is only very slightly higher). However, given our desire to check for structural change, especially around the time of the recent financial crisis, we repeat our estimation on a reduced sample ending in 2008q3, therefore excluding the crisis itself. Table 1 shows the OLS results (which assume constant coefficients).

Table 1: OLS estimates

The OLS results strongly support the use of current expectations of future inflation in the Phillips curve, while previously expected current inflation is

insignificant. The other explanatory variables are mostly of theoretically-sensible sign or are found to be insignificant. This is as one would expect if we are including too many correlated predictors and the predictor set is changing over time. Preliminary evidence that the crisis affects the estimated parameters can be found by comparing the estimates in the two subsamples: while many coefficients look relatively robust to the sample choice, others (such as the expectation uncertainty, the short-term interest rate or the stock market index) change significance or sign in the two regressions. Accordingly, we turn to DMA results which can ensure more parsimony as well as switching between different sets of predictors.

We implement DMA based on Koop and Korobilis (2011) and equation (6). The specification of a DMA requires: i) a prior for the parameters, ii) a prior over the initial model probabilities and iii) a choice for the forgetting factor. We use i) a noninformative prior over the parameters, ii) make the noninformative choice of  $q_{0|0,j} = \frac{1}{K}$  for  $j = 1, \dots, K$  and iii) set  $\alpha = 0.99$ . We initialize with OLS results (including all the predictors) using the initial three years of data, before doing DMA on the remainder of the sample. Posterior inference in the regression model using a noninformative prior involves standard textbook formulae (e.g. Koop, 2003, pages 36-38). The predictive density, which plays a crucial role in DMA via (4), also has a textbook formula (e.g. Koop, 2003, page 46).

Our regression model has 14 predictors (i.e. the 8 explanatory variables listed in Section 4.1, four lags of the dependent variable and past and current inflation expectations) and, in light of our small sample size, a first question of interest is whether DMA is being parsimonious. Figure 1 sheds light on this. It plots the expected size of the models used by DMA at each point in time where

$$E(Size_t) = \sum_{k=1}^K q_{t|t-1,k} Size_k,$$

and  $Size_k$  is the number of predictors in model  $k$ . It can be seen that DMA is being fairly parsimonious. That is, it could have included 14 predictors but tends to be choosing roughly half of them. Furthermore, there is some variation over time.

In order to see which predictors are being chosen by DMA, Figures 2 through 5 plot time-varying posterior inclusion probabilities associated with every explanatory variable. These are the probabilities allocated by DMA to models which contains each predictor (i.e. for the  $j^{th}$  predictor this is

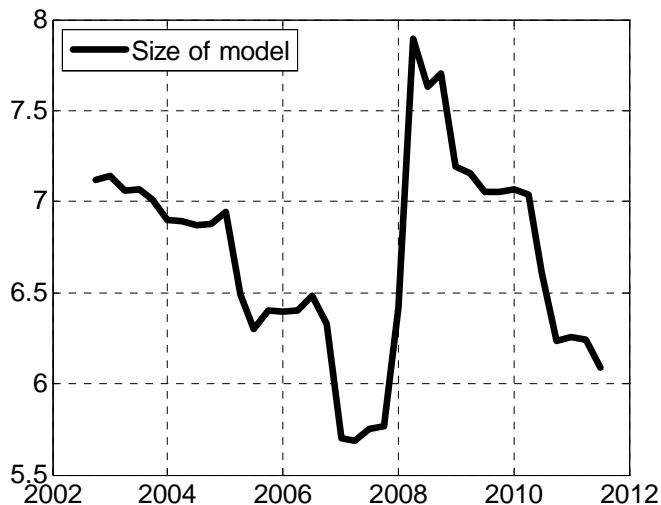

Figure 1: Expected Size of Models Chosen by DMA

$\sum_{i \in j} q_{i|t,i}$  where the summation is over all models which include the  $j^{th}$  predictor). Note that, near the beginning of the sample, there will be little information to estimate the posterior inclusion probabilities and, hence, it is possible that they differ little from their prior inclusion probability of  $\frac{1}{2}$  (i.e. a priori, we assume each explanatory variable is equally likely to be included as excluded from the model, which is a standard noninformative choice). Similar considerations hold for any other model feature (e.g. such as regression coefficients) which will tend to be imprecisely estimated early in the sample. In Figures 2 through 5 we find most posterior inclusion probabilities to begin near  $\frac{1}{2}$ . However, after this initial period, there is a wide variation in behaviors across predictors. In some cases, the weight attached by DMA is gradually changing over time. But in other cases, probabilities are switching very abruptly as DMA decides to include/exclude a variable at a particular point in time. For instance, for most of the early sample, variables measuring changes in wages and oil prices (ULC and OIL) are relatively unimportant. However, in 2008 they switch to becoming important right before the crisis, only to be omitted afterwards in favor of financial variables and interest rates. In general, there is uncertainty over which predictor is

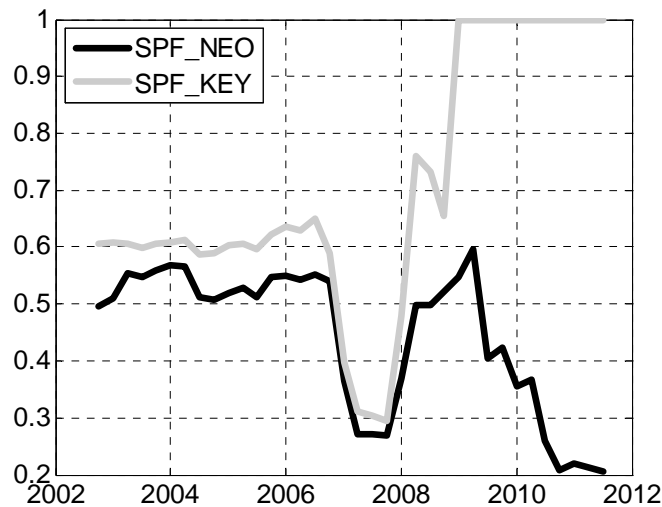

Figure 2: Time Varying Probability of Inclusion of Inflation Expectations Variables

important at each point in time. A method such as DMA is an appropriate method of dealing with this uncertainty.

Given our interest in the expectations and the Phillips curve, Figure 2 is an important graph. It shows that previously expected current inflation, although not completely excluded by DMA, is relatively unimportant. This finding is consistent with our OLS results of Table 1. The posterior inclusion probability of the forward looking inflation expectations variable is also consistent with the OLS results. However, it adds an important refinement in our understanding of the role of inflation expectations in the Phillips curve. That is, DMA is finding  $\pi_{t+4|t}^e$  to be a very important predictor of inflation, but its importance greatly increases only near the end of the sample. Until 2006, we are finding it to be about as important as the previously expected current inflation. As of 2006, we witness a first regime shift: the economy of the euro zone is subject to a wide range of external shocks, as indicated by the increasing importance of the oil variable (Figure 5) between 2006 and 2008.

It is also interesting to note that our measure of uncertainty, SPFVAR, does not seem to have important explanatory power for inflation.

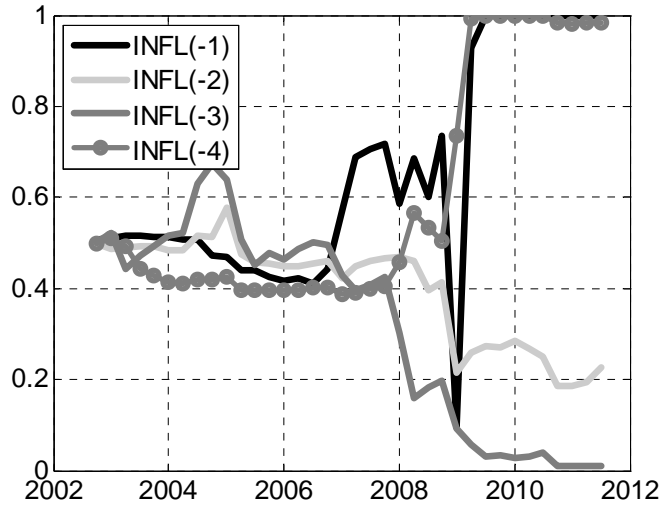

Figure 3: Time Varying Probability of Inclusion of Lagged Dependent Variables

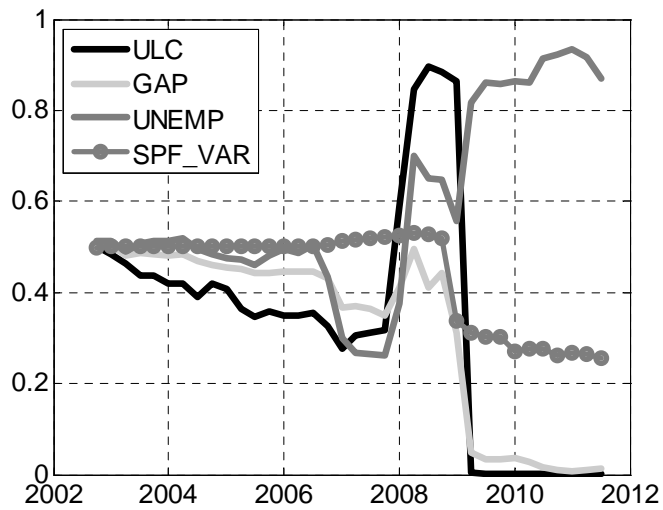

Figure 4: Time Varying Probability of Other Explanatory Variables

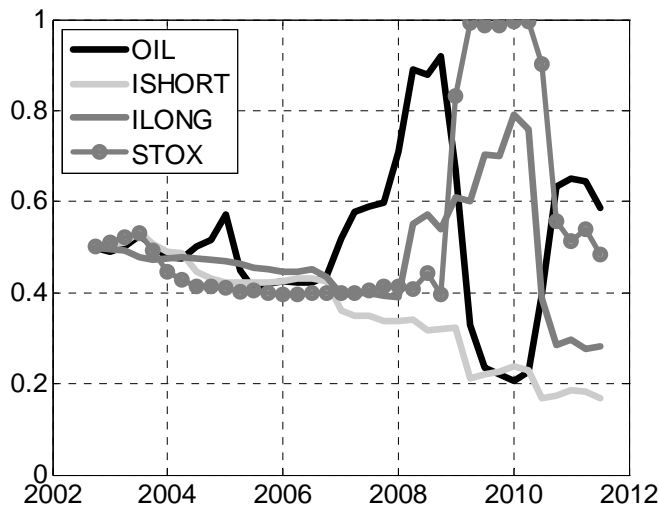

Figure 5: Time Varying Probability of Other Explanatory Variables

An examination of Figures 6 and 7 reinforces these findings relating to the coefficients on  $\pi_{t|t-4}^e$  and  $\pi_{t+4|t}^e$ . These plot the posterior mean and  $\pm$  two posterior standard deviation intervals for each of these coefficients. The posterior mean for the coefficient on past expectations is slightly positive but near zero (which is more reasonable than the negative OLS estimate of Table 1). The  $\pm$  two posterior standard deviation interval narrows over time as the incorporation of new data allows for more precise estimation. However, at all points in time zero is well within this interval. Until 2008, Figure 7 shows a similar pattern for the coefficient of current expectations. But in 2008 the posterior mean abruptly jumps to being approximately one (as we found with the OLS estimate) and the  $\pm$  two posterior standard deviation interval does not include zero.

The regression results presented in this sub-section tell a consistent story. It is current expectations which are most important in the Phillips curve. Our DMA results also suggest that their importance is greatest at the end of our sample, at the time of the financial crisis and ensuing recession.

The change in importance of different regressors provides, in our opinion, a coherent explanation of the determinants of inflation dynamics before and during the crisis. First of all, the oil price shocks affecting prices as

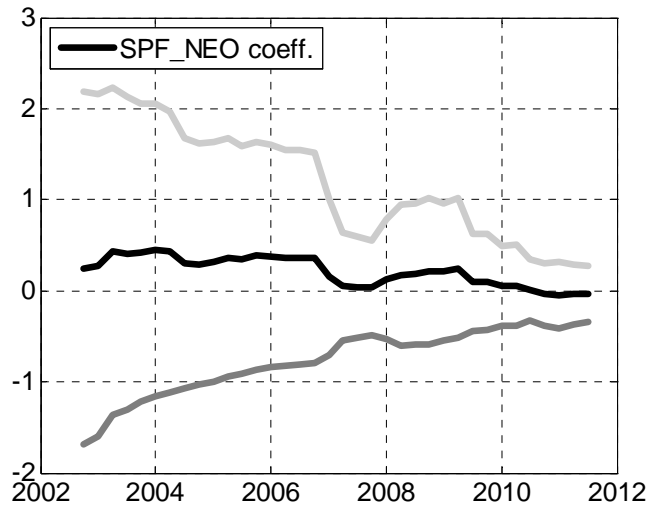

Figure 6: DMA Posterior of SPF\_NEO Coefficient (post. mean and +/- 2 st. dev. bands)

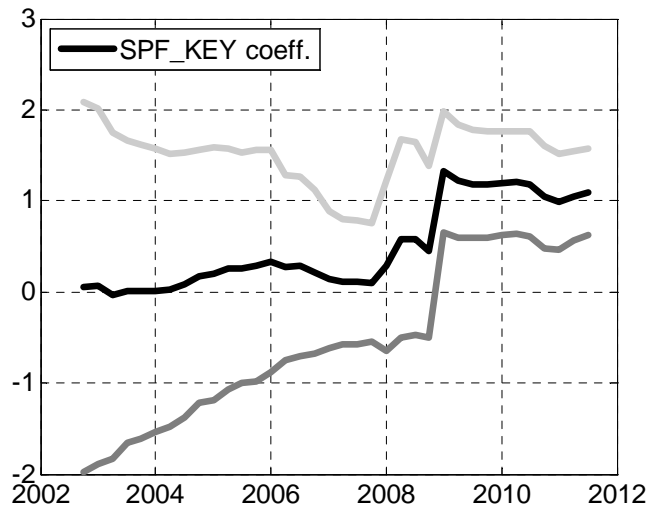

Figure 7: DMA Posterior of SPF\_KEY Coefficient (post. mean and +/- 2 st. dev. bands)

of 2006 are clearly visible in the increasing importance of the oil variable in the period 2006/2008. At the same time, and in a period of strong and unpredictable shocks, sizeable errors in the agents expectations reduce their inclusion probability. When the global crisis hits in 2008, this time in the context of coherent macroeconomic developments, the regressors representing fundamentals seem to be again more important, either as direct explanatory variables (short and long interest rates and financial markets developments) or through current expectations of future inflation, which are computed by the agents keeping it into account a much wider information set than the one included in our regressions. In particular, the unemployment rate becomes the most important and reliable indicator of economic conditions, confirming the arguments about the resurgence of the Phillips curve and the claim by Stock and Watson (1999) and Amisano and Giacomini (2007) that the unemployment rate has strong advantages in terms of forecast accuracy in a model for inflation.

Finally, from 2006 onwards the more unpredictable inflation developments determine an increase of the importance of the first lag of inflation, leading to models somewhat closer to a random walk. We next turn to VAR-based methods as a way of obtaining a deeper understanding of this process.

#### 4.4 Multivariate VAR-based Methods

For the reasons outlined in Section 4.1 we are also interested in modelling inflation and an expectation of inflation jointly. To do this, we use DMA methods applied to VARs with exogenous explanatory variables:

$$y_t = a + \sum_{j=1}^p A_j y_{t-j} + B X_t + \varepsilon_t, \quad (7)$$

where  $y_t = \left( \pi_{t+4|t}^e, \pi_t \right)'$  or  $y_t = \left( \pi_{t|t-4}^e, \pi_t \right)'$  and  $X_t$  is the vector of eight explanatory variables listed in Section 4.1,  $B$  is a matrix of regression coefficients and  $\varepsilon_t$  is independent  $N(0, \Sigma)$ . To our knowledge, DMA has never been used with VARs. Accordingly, the development of some new econometric techniques is required. These are explained in the appendix in detail. It suffices to note here that the DMA is done in a similar way as with the regression model. Equation (7) defines an unrestricted VAR with exogenous variables  $X_t$  which appear in every equation. Our model space contains restricted versions of this model defined by whether explanatory variables are

included/excluded. In terms of  $X_t$ , we allow for this to be done one equation at a time. That is, it would be simplest if we only considered restricted models defined by whether an element of  $X_t$  is included/or excluded in all equations. We do not adopt this simple strategy, but consider the full possible set of restricted models (i.e. we also allow for restricted models where an explanatory variable is included in one equation, but not the other). However (to keep the computational burden manageable), we do not do DMA on the VAR part of the model (i.e. all models include the intercept and VAR lags). As with our regression methods, we use a noninformative prior for the parameters of each model, set  $\alpha = 0.99$  and initialize using OLS results (in a VAR including all the predictors) using the initial three years of data, before doing DMA on the remainder of the sample. DMA is based on predictive likelihoods (see Section 4.2 or the appendix) which can be used as a model selection device. We use the product of the predictive likelihoods over all periods (except for the initial three years) to choose lag length and found evidence in favor of  $p = 1$  for both definitions of the dependent variables and we adopt this choice in this sub-section. Given the need to include one lag of the SPF variables in the VAR, we estimate using one less observation than in our regressions and the data begins in 2000Q1.

To motivate our VAR specifications, note that structural VARs are usually written as:

$$C_0 y_t = c_0 + \sum_{j=1}^p C_j y_{t-j} + DX_t + u_t$$

where  $u_t$  is i.i.d.  $N(0, I)$ . A choice of  $C_0$  identifies the model and allows for a structural impulse response analysis. If  $y_t = \left( \pi_{t+4|t}^e, \pi_t \right)'$  then a specification motivated by the hybrid New Keynesian Phillips curve in (2) arises if  $C_0$  is lower triangular. That is, the second equation in the structural VAR is a Phillips curve relationship between  $\pi_t$  and  $\pi_{t+h|t}^e$  (including additional lags as in the hybrid version and extra exogenous variables as in the generalized Phillips curve). The fact that  $\pi_{t+4|t}^e$  is ordered first in the identification scheme is motivated by the fact that the SPF is carried out in the first month of the quarter (so that  $\pi_t$  will not have been observed when the forecasts  $\pi_{t+4|t}^e$  are made). Clark and Davig (2008) adopt the same identification scheme in an application involving US surveys. In a similar fashion, when investigating the Neoclassical Phillips curve we use a VAR with  $y_t = \left( \pi_{t|t-4}^e, \pi_t \right)'$ , but the

same identification scheme (i.e.  $C_0$  is lower triangular with  $\pi_{t|t-4}^e$  ordered first) is used.

We will refer to the VAR with dependent variables  $\pi_{t+4|t}^e$  and  $\pi_t$  as the New Keynesian VAR and to the VAR with dependent variables  $\pi_{t|t-4}^e$  and  $\pi_t$  as the Neoclassical VAR. Given our recursive estimation procedure, impulse responses will change over time. Accordingly, we have different impulse responses in every time period. Figures 8 through 11 plot the one year impulse responses for the New Keynesian VAR against time. Figures 12 through 15 do the same for the Neoclassical VAR.

The most important figures are 9 and 13 which show how inflation responds to different expectations variables. These figures convey a message similar to the one found when doing DMA in the single equation regression. As implied by the New Keynesian Phillips curve, current expectations of future inflation do have an important impact on inflation. However this impact only becomes statistically relevant (and increasingly substantial) just before the financial crisis begins in 2008. In the Neoclassical VAR, on the other hand, the expectation variable is only occasionally significant (briefly in 2009 and in 2011), and even in these periods the estimated coefficients is small and switches sign over time.

Figures 10 and 14 allow us to investigate the reverse effect: whether inflation has an impact on expectations. Remember that our structural VAR is identified by assuming that inflation has no immediate impact on inflation expectations. The New Keynesian impulse response in Figure 10 is never significant, with the only exception of early 2009. A counterintuitive finding is obtained in the Neoclassical VAR, where the impulse response is not significant or is negative but (with the exception of early 2009) extremely small. It is worth noting that 2009 was the most unusual year in our sample. Inflation was less than one percent in every quarter of the year and was actually negative in 2009Q3. In no other quarter in our sample was inflation ever less than one percent. Expectations of the profession forecasters were substantially off: the one year ahead forecasts made in the four quarters of 2008 were 2.13, 2.4, 1.95 and 1.44, respectively. Thus, in 2008 the SPF forecasters only gradually lowered their inflation forecasts and, in 2009, they turned out to have been much too high. The current forecasts of future inflation were much better. That is, in the four quarters of 2009 the one year-ahead forecasts were 1.17, 1.21, 1.29 and 1.37 which were much closer to both the contemporaneous 2009 inflation realizations and the 2010 realizations.

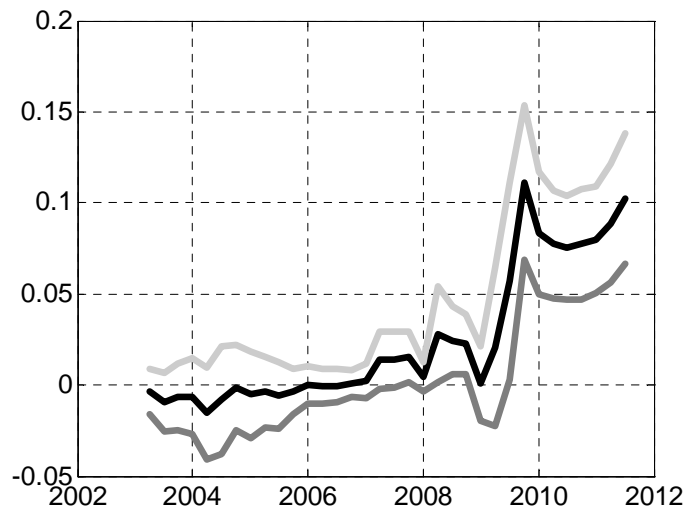

Figure 15: Neoclassical VAR, Impulse response of Inf to Inf Shock (post. mean +/- 1 st. dev.)

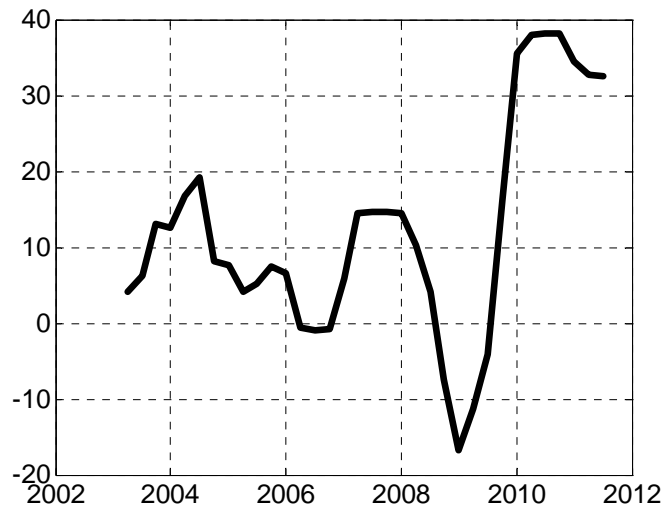

Figure 16: Difference in Cumulative log Pred. Likelihoods: New Keynesian minus Neoclassical VAR

The New Keynesian and Neoclassical VAR cannot be directly compared using standard model comparison methods since they have different dependent variables. However, if we consider only the inflation equation, then the models are comparable. For the New Keynesian and Neoclassical VARs, the sums of log predictive likelihoods (obtained from the DMA exercise) for only inflation equation are 156.35 and 123.78, respectively. This provides strong evidence that the New Keynesian VAR is much better at explaining inflation than the Neoclassical one.

To gain more insight on when the superior performance of the New Keynesian Phillips curve is occurring, Figure 16 presents cumulative sums of log predictive likelihoods for the inflation equation. In most of the sample the New Keynesian VAR performs better than the Neoclassical VAR. The only exception is a short period between the end of 2008 and the beginning of 2009, when at the very beginning of the crisis all expectations are performing equally bad and the Neoclassical framework is preferred. However, after the financial crisis settles into the expectations, the New Keynesian VAR pulls ahead and obtains a much higher log predictive likelihood.

## 5 Conclusions

In this paper we perform different empirical exercises, both single-equation and multivariate, as a way of investigating the relationship between inflation and inflation expectations in the euro area and how this relationship changes with time. The estimated results in the literature differ according to the chosen specification; our technique provides a robust estimation, since all possible models are taken into consideration and subsequently averaged. We use the forecasts from the ECB's Survey of Professional Forecasters as a proxy for inflation expectations and investigate the information content of the survey.

Overall, the paper confirms that there have been shifts in the Phillips curve and suggests the following conclusions.

First, we find that SPF-based forward looking inflation expectations are an important source of information, thus supporting the New Keynesian Phillips curve. This evidence is concentrated in the final part of the sample, after the beginning of the crisis.

Second, and in analogy to the findings of Stock and Watson (2008) for the U.S., the crisis has "revived" the Phillips curve in the euro area. Unemployment, rather than output gap, is the best indicator of cyclical condition, a non surprising result given the high measurement uncertainty of the latter. The other important determinants of prices, long term interest rates and stock market index, confirm that the shocks leading to the crisis are of financial nature.

Third, before the crisis one can distinguish between a "stable inflation" subsample, ending in 2006, in which the high stability of inflation and expectations even lead to a slight predominance of the Neoclassical framework, and an "external shocks" subsample in which important fluctuations in oil prices and other international commodities are the main drivers of inflation developments and all expectations perform poorly.

The informal but clear identification of three different periods in the reduced time span of our analysis should be important to forecasters and policy makers. It shows that there is no thing as a stable environment, and therefore no stable model. How to best model such changes in real time is an open issue, but our results underline the importance of introducing informed judgment in forecasting models and of changing such judgment frequently to adapt the models to the prevailing economic conditions.

The instability of the Phillips curve is also important for the conduct of monetary policy, as the estimates highlight changes in the effect of expecta-

tions on inflation and a resurgence of the “sacrifice ratio”.

Finally, the SPF is a relatively new data source and, thus, econometric methods designed to deal with the short data span were required. However, our empirical exercises suggest that there is information in the SPF than can be fruitfully used by macroeconomists and policymakers.

## Appendix: Dynamic Model Averaging in VARs

In this paper, we consider  $M$  different models which are all VARs with  $k_x$  exogenous explanatory variables. Formally, each model can be written, for  $t = 1, \dots, T$  and  $m = 1, \dots, M$ , as

$$y_t = Z_t^{(m)} \theta^{(m)} + \varepsilon_t^{(m)}, \quad (8)$$

where  $y_t$  is an  $N \times 1$  vector of dependent variables,  $\varepsilon_t^{(m)} \stackrel{ind}{\sim} N(0, \Sigma^{(m)})$ ,

$$Z_t^{(m)} = \begin{pmatrix} z_{1t}^{(m)} & 0 & \dots & 0 \\ 0 & z_{2t}^{(m)} & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & z_{Nt}^{(m)} \end{pmatrix},$$

$z_{nt}^{(m)} = (1, y'_{t-1}, \dots, y'_{t-p}, x_{nt}^{(m)})$  for  $n = 1, \dots, N$  and  $x_{nt}^{(m)}$  is a row vector of explanatory variables in the  $n^{th}$  equation of model  $m$  and  $h$  is the forecast horizon.  $x_{nt}^{(m)}$  will be a subset of  $k_x$  potential explanatory variables. In the paper, these are the eight explanatory variables listed in Section 4. 1.

Note that our models all have a basic VAR(p) structure, but allow for different for different equations to have different explanatory variables among those included. Allowing for each of the  $k_x$  potential explanatory variables to be included in each of  $N$  equations means our model space contains  $M = 2^{Nk_x}$  models.

In this paper, we wish to investigate whether the model used for explaining  $y_t$  is changing over time. Thus, we use a restricted version of the dynamic model averaging (DMA) methods developed by Raftery, Karny and Ettl (2010) and used by Koop and Korobilis (2011). Ours is a restricted version in the sense that Raftery et al. (2010) allow for time variation in the coefficients (i.e. they replace our constant  $\theta^{(m)}$  by a state equation  $\theta_{t+1}^{(m)} = \theta_t^{(m)} + \eta_t^{(m)}$ ). Over our relatively short data span, estimating time variation in coefficients seemed too much to ask from our short data set. We estimate our model recursively which allows for some time variation in the coefficients and to some extent model change can be a substitute for parameter change. Note, though, that previous work with DMA has only been for the regression case ( $N = 1$ ) and our use of DMA methods with VARs pushes DMA in a new direction.

Two key components required by DMA are: i) formula for Bayesian inference in each model and, ii) formula for the predictive density  $p_k(y_t | y^{t-1})$

so as to calculate (4). With these, recursive updating using (4) and (5) can be used to produce  $q_{t|m}$  for  $m = 1, \dots, M$  exactly as for regression case.

A slight complication arises since our models are restricted VARs and, hence, an analytical formula for posterior and predictive density does not exist and MCMC methods are typically required (see, e.g., Koop and Korobilis, 2009). Given the computational demands required by working with  $M = 2^{Nk_x}$  models, it is not possible to use MCMC methods for evaluating each model. Hence, we use approximate methods. We replace  $\Sigma$  by the usual OLS estimate. An analytical formula for the posterior of the VAR coefficients, conditional on an estimate of  $\Sigma$ , is available (see page 284 of Koop and Korobilis, 2009, for the exact formula). The predictive density (conditional on  $\Sigma$ ) is a Normal distribution with mean and covariance taking the formula on page 278 of Koop and Korobilis (2009).

In summary, this appendix defines our model space which is a set of restricted VARs. DMA is done as described in the body of the paper, however involving VARs and relevant formulae for the predictive densities. These details have been provided in this appendix.
